Abstract

On the basis of the recently estimated emission inventory for East Asia with a resolution of $1 \times 1^\circ$, the transport and chemical transformation of sulfur compounds over East Asia during the period of 22 February through 4 May 2001 was investigated by using the Models-3 Community Multi-scale Air Quality (CMAQ) modeling system with meteorological fields calculated by the regional atmospheric modeling system (RAMS). For evaluating the model performance simulated concentrations of sulfur dioxide (SO$_2$) and aerosol sulfate (SO$_4^{2-}$) were compared with the observations on the ground level at four remote sites in Japan and on board aircraft and vessel during the transport and chemical evolution over the Pacific and Asian Pacific regional aerosol characterization experiment field campaigns, and it was found that the model reproduces many of the important features in the observations, including horizontal and vertical gradients. The SO$_2$ and SO$_4^{2-}$ concentrations show pronounced variations in time and space, with SO$_2$ and SO$_4^{2-}$ behaving differently due to the interplay of chemical conversion, removal and transport processes. Analysis of model results shows that emission was the dominant term in regulating the SO$_2$ spatial distribution, while conversion of SO$_2$ to SO$_4^{2-}$ in the gas phase and the aqueous phase and wet removal were the primary factors that controlled SO$_4^{2-}$ amounts. The gas phase and the aqueous phase have the same importance in oxidizing SO$_2$, and about 42% sulfur compounds (~25% in SO$_2$) emitted in the model domain was transported out, while about 57% (~35% by wet removal processes) was deposited in the domain during the study period.

Keywords: Long-range transport; SO$_2$; Sulfate; ACE-Asia; Chemical transport model
1. Introduction

Sulfur dioxide (SO$_2$) is one of the most important individual precursor compounds for secondary matter in the atmosphere. Aerosol sulfate (SO$_4^{2-}$) has been identified as an important contributor to the scattering of sunlight, and a major component of cloud condensation nuclei (Lelieveld and Heintzenberg, 1992; Chuang et al., 1997). In addition to these, sulfate is an important acidifying agent and a potential cause of adverse health effects observed in urban areas (Rodhe, 1999). Sulfur compounds are especially important in East Asia in view of the fact that pollutant emission has been continuously and rapidly increasing over the last decades (e.g., Streets et al., 2000) and is expected to continue to increase in the coming decades, e.g., SO$_2$ emissions in China are projected to increase from 25.2 mt (million ton) in 1995 to 30.6 mt in 2020, provided emission controls are implemented on major power plants (Streets and Waldhoff, 2000), and they can be transported long distance up to several thousand kilometers.

SO$_4^{2-}$ is primarily produced from the oxidation of SO$_2$, and the conversion of SO$_2$ to SO$_4^{2-}$ occurs via multiple pathways, including gas-phase oxidation to sulfuric acid (H$_2$SO$_4$) followed by condensation into the particulate-phase, aqueous-phase oxidation in cloud or fog droplets, and various reactions on the surfaces or inside aerosol particles. In the last two decades a variety of transport and acid deposition models have been developed or applied to address sulfur transport, transformation and deposition over East Asia (e.g., Ichikawa et al., 1998; Xu and Carmichael, 1999; Murano et al., 2000; Qian et al., 2001; Kim et al., 2001). This study is another attempt to investigate the behavior of SO$_2$ and SO$_4^{2-}$ over East Asia at the range of temporal and spatial scales, and to examine the relative role of emission, meteorological fields, chemical and removal mechanisms in regulating this behavior with a comprehensive chemical transport model on the basis of a newly estimated emission inventory for East Asia with a resolution of $1 \times 1^\circ$ prepared specially to support the transport and chemical evolution over the Pacific (TRACE-P; Jacob et al., 2003) and the Asian Pacific Regional Aerosol Characterization Experiment (ACE-Asia; Huebert et al., 2003) and large observational data sets obtained at four remote sites as an East Asia Acid Rain Monitoring Network (EA-net) in Japan and on board aircraft and ship during TRACE-P and ACE-Asia field campaigns. The extensive data collected during TRACE-P and ACE-Asia can be downloaded from websites http://www-gte.larc.nasa.gov/gte_fld.htm and http://www.joss.ucar.edu/cgi-bin/codiac/ds_project/ACE-ASIA.

In Section 2 we briefly describe the model, its initial and boundary conditions, and emission inventories, and in Section 3 we firstly compare modeled SO$_2$ and SO$_4^{2-}$ mixing ratios with observations and discuss their temporal and spatial concentration distributions, and then examine the relative importance of different physical and chemical processes in determining SO$_2$ and SO$_4^{2-}$ concentrations, the Conclusion is given in Section 4.

2. Model description

The transport and chemical evolution of sulfur compounds over East Asia is investigated by use of the Models-3 Community Multi-scale Air Quality (CMAQ) modeling system (Byun and Ching, 1999). CMAQ is an Eulerian-type model developed in the US Environmental Protection Agency to address tropospheric ozone, acid deposition, visibility, particulate matter and other pollutant issues in the context of “one atmosphere” perspective where complex interactions between atmospheric pollutants and regional and urban scales are confronted. CMAQ has recently been successfully applied to East Asia to simulate tropospheric ozone and carbon monoxide (Zhang et al., 2002, 2003).

The current version of the model is configured with the chemical mechanism of the regional acid deposition version 2 (RADM2; Stockwell et al., 1990), including gas-phase and aqueous chemistry and having been extended to include the four-product Carter isoprene mechanism (Carter, 1996) and aerosol processes from direct emissions and production from sulfur dioxide, long-chain alkanes, alkyl-substituted benzene, etc. To depict aerosol evolution processes in the atmosphere, the aerosol module, a major extension of the Regional Particulate Model (RPM; Binkowski and Shankar, 1995) is included. In the module the particle-size distribution is represented as the superposition of three lognormal sub-distributions, and the processes of coagulation, particle growth by the addition of new mass, particle formation, dry deposition, cloud processing, aerosol chemistry, etc. are included. The complete mechanisms with lists of species and reactions in the model are described in detail by Byun and Ching (1999).

For CMAQ, the anthropogenic emissions of nitrogen oxides, carbon monoxide, volatile organic compounds (VOCs) and SO$_2$ were obtained from the emission inventory of $1 \times 1^\circ$ specially prepared by scientists at the Center for Global and Regional Environmental Research at the University of Iowa (Streets et al., 2003) to support TRACE-P and ACE-Asia and from the emission database for global atmospheric research (EDGAR; Oliver et al., 1996). NO$_x$ emissions from soils and natural hydrocarbon emissions were obtained from the global emissions inventory activity (GEIA) $1 \times 1^\circ$ monthly global inventory (Benkovitz et al., 1996) for the month of March. VOC emissions were
apportioned appropriately among the lumped-hydro-carbon categories used in RADM2. Natural sources consist of the active volcanic sources in the region. The emissions from the largest erupting volcano of Miyake-jima, located to the south of Tokyo, were updated based on the flux measurements (http://staff.aist.go.jp/kazahaya-k/miyakegas/COSPEC.html). The SO$_2$ emissions from this volcano eruption contributed two-thirds of the total SO$_2$ emitted over Japan. In this study it is assumed that 5% SO$_2$ emitted was in the form of H$_2$SO$_4$.

The three-dimensional meteorological fields needed by CMAQ are provided by the Regional Atmospheric Modeling System (RAMS). In this study, RAMS is exercised in a four-dimensional data assimilation mode using analysis along with re-initialization every 4 days, leaving first 24 h as initialization period. The three-dimensional meteorological fields for RAMS were obtained from the European Center for Medium-Range Weather Forecasts (ECMWF) analyzed datasets, and were available every 6 h with 1° resolution. Besides, sea surface temperatures for RAMS were based on weekly mean values and observed monthly snow-cover information as the boundary conditions for the RAMS calculation.

The study domain (shown in Fig. 1) is $6240 \times 5440$ km$^2$ on a rotated polar-stereographic map projection centered at (25°N, 115°E) with 80 km grid cell. For RAMS there are 23 vertical layers in the $s_z$ coordinates system unequally spaced from the ground to ~23 km, with about 9 layers concentrated in the lowest 2 km of the atmosphere in order to resolve the planetary boundary layer, while there are 14 levels for CMAQ with the lowest 7 layers being the same as those in RAMS.

Initial and boundary conditions of species were chosen to reflect the East Asian situation. Recent measurements were used whenever possible (Zhang et al., 2003). To evaluate the impact of the anthropogenic emissions on the distributions of trace gases and aerosols, the initial and boundary conditions were generally chosen at the lower end of their observed range (e.g., the northern and western boundary conditions for SO$_2$ and SO$_4^{2-}$ were 0.3 ppbv and 1 µg m$^{-3}$, respectively) so as to allow the emissions and chemical reactions to bring them closer to their actual values during the initialization period (Liu et al., 1996; Carmichael et al., 1998).

In order to trace the Miyakejima volcano plume behavior, we also used the Lagrangian particle model (RAMS/HYPACT: Hybrid particle and concentration transport model, Walko et al., 2001) to simulate the volcano-emitted SO$_2$ transport and diffusion processes. In this model it assumed that SO$_2$ is converted to SO$_4^{2-}$ at a constant rate of 1% h$^{-1}$ since SO$_2$ is released. RAMS-calculated meteorological results were used in HYPACT dispersion calculation, and the SO$_2$ emission rate from the Miyakejima volcano was assumed constant. HYPACT-calculated SO$_2$ concentration fields will be discussed with CMAQ modeled SO$_2$ and SO$_4^{2-}$ concentration fields in Section 3.1.

3. Model results and discussion

The simulation period covers 22 February–5 May 2001 with starting time at 0000 Z on 22 February i.e., 0900 JST (Japanese Standard Time), when the TRACE-P and the ACE-Asia missions were being conducted over the Western Pacific Ocean, it provides extensive observational data to evaluate the model performance and further to quantify the spatial and vertical distribution of SO$_2$ and SO$_4^{2-}$, the processes controlling their formation, evolution and fate.

3.1. Transport and chemical evolution of SO$_2$ and SO$_4^{2-}$ in the boundary layer

The meteorological situation is genuinely central to the distribution of many atmospheric chemical species (Merrill et al., 1997). This is because meteorological parameters impact both the chemical processes and the transport phenomena, which govern the evolution of these distributions. Comparison of the meteorological parameters (such as wind speed and direction, temperature and water mixing ratio) simulated by RAMS with airborne measurements on board NASA aircraft DC-8 and P-3B (Jacob et al., 2003) and NCAR aircraft C-130 (Huebert et al., 2003) showed that the modeled meteorology reproduced quantitatively most of the major observed features (Uno et al., 2003). For example,
the correlation coefficients for wind speed, temperature and relative humidity each exceeded 0.9 for all TRACE-P observation points for altitudes below ~5 km.

Spring is the season of maximum Asian outflow over the Pacific due to a combination of active convection over the continent and strong westerlies, and the intermittent SO2 peaks observed at four remote sites in Japan shown in Fig. 2 suggest that Asian outflow is highly episodic (Yienger et al., 2000). It shows the time variations of hourly averaged SO2 concentrations measured at the sites (EA-net) of Hedo (Fig. 2a), Oki (Fig. 2b), Happo (Fig. 2c), and Sado (Fig. 2d). Also shown are the results from the model for the lowest model layer, approximately 150 m above the ground. The locations of the observation sites are shown in Fig. 1.

From Fig. 2 we can see that the model captures the time variation of SO2 mixing ratios in the simulation period very well, and in most cases simulated and observed concentrations are in good agreement, for example, the magnitude and timing of the peak SO2 levels around Julian Day (JD) 100 (i.e., 10 April) at all four sites were well captured, while some simulated SO2 spikes at Hedo around JD 78 (i.e., 19 March) and 116 (i.e., 26 March) are not well seen in observations, and some observed elevated values at four sites are not reproduced in simulations (e.g., JD 70–73, 83 at Oki). As SO2 is mostly emitted in the continental boundary layer, and its concentrations at these remote sites are primarily dependent on transport processes, so the good agreement between simulated and observed SO2 mixing ratios implies that the SO2 emissions, wind fields and transport processes were reasonably well treated in the RAMS and CMAQ model.

During the ACE-Asia mission, NOAA Research Vessel Ronald H. Brown (RonBrown) made continuous observations around Japan. Its ship track and observed concentrations of SO2 and SO4^-2 are presented in Fig. 3. The methods used for SO2 and SO4^-2 analysis are described in Bates et al. (2004). Also shown in the figure are simulated hourly averaged concentrations sampled along the ship track. Fig. 3 shows high SO2 mixing ratios (up to 35 ppbv) over the area south of Tokyo around JD 90 (i.e., 31 March) and 109 (i.e., 19 April) and over the Sea of Japan around JD 100 (i.e., 10 April), and high SO4^-2 mixing ratios over the Sea of Japan around JD 100.

Fig. 2. (a–d) Time series of measured (solid dots) and modeled (solid lines) SO2 mixing ratios at four remote sites Sado, Happo, Oki and Hedo in Japan.
(10 April). High SO$_2$ and low SO$_4^{2-}$ concentrations over the area south of Tokyo clearly shows the area was under strong influence of fresh SO$_2$ plume from the Miyakejima volcano, and the model reproduces this observed feature quite well. High SO$_2$ and SO$_4^{2-}$ concentrations over the Sea of Japan are also captured by the model and are identified to be associated with the emissions from the Miyakejima area just south of Tokyo, Japan. High SO$_2$ values over the Sea of Japan were associated with the Miyakejima volcano emissions (see Fig. 6a), which is clearly shown in the figure. From Figs. 2b–d and 3b we can see elevated SO$_2$ values at Oki, Happo, Sado and over the Sea of Japan at this time. The SO$_2$ dispersion calculation results shown in Fig. 6 clearly shows the impact of Miyakejima volcano reached to the western part of the Japan area and it has a good agreement with the surface SO$_2$ peak.

The horizontal distributions of SO$_4^{2-}$ mixing ratios shown in Fig. 5a are generally consistent with those of SO$_2$ where its mixing ratios are high, i.e., elevated SO$_4^{2-}$ concentrations are also seen in Sichuan Province, Shanghai and Beijing areas in China, Seoul and Pusan areas in South Korea and over the Sea of Japan. Obvious differences between Figs. 4a and 5a are seen over the western Pacific and the inner Asian continent covering northwestern China and Mongolia. Over the western Pacific we observe that SO$_2$ levels are lower than 0.1 ppbv while SO$_4^{2-}$ values are higher than 1 $\mu$g/m$^3$. In contrast, over the inner Asian continent SO$_2$ values are higher than 0.1 ppbv while SO$_4^{2-}$ values are lower than 1 $\mu$g/m$^3$. These differences are primarily associated with different weather and chemical conditions and are seen in the next 3 days. As temperature and water contents in the surface air over the western Pacific are higher than over the inner Asian continent, and concentrations of hydroxyl radical (OH) and hydrogen peroxide (H$_2$O$_2$) are also higher (horizontal distributions of OH and H$_2$O$_2$ mixing ratios are not shown here), so SO$_2$ is oxidized faster via the gas phase and the aqueous phase over the western Pacific than over the inner Asian continent, and coordinately SO$_4^{2-}$ concentrations are higher over the western Pacific as it is primarily produced from the oxidation of SO$_2$. Besides, high SO$_4^{2-}$ concentrations over the western Pacific may be partially attributed to its direct transport from the continent.

On 10 and 11 April (i.e., JD 100 and 101) central and eastern China was under influence of a high pressure located in northwestern China and the low pressure
Fig. 4. (a)–(e) Horizontal distributions of SO$_2$ mixing ratios (ppbv) and wind vectors for the lowest model layer (~150 m above the ground) at 1200 JST (Japanese Standard Time) on 9–13 April, and (f) height (km)—longitude distribution of SO$_2$ mixing ratios at latitude ~30°N at 1200 JST on 12 April.
Fig. 5. (a–f) Same as Fig. 4 but for $\text{SO}_4^{2-}$ ($\mu$g m$^{-3}$).
Fig. 6. (a–e) Horizontal distributions of vertically averaged HYPACT calculated SO$_2$ concentrations at 1200JST on 9–13 April.
moved eastward from the Okinawa area. We see in Figs. 4b, c, 5b and c that over southern Japan and the area to the south of Japan, strong northeast winds sweep SO$_2$ and SO$_4^{2-}$/C$_0$ to East China Sea and Okinawa area, while anticyclonic circulation over the Asian continent pushes pollutants within the continent out to sea, then brings them southward.

Figs. 4b and 6b indicate that Oki is experiencing high SO$_2$ levels associated with the volcano plume, and the observations recorded the highest SO$_2$ concentrations at Oki (Fig. 2b). On 10 April high SO$_2$ values appeared at Happo (Fig. 2c) and on the next day at Hedo (Fig. 2a).

On 12 April (i.e., JD 102) a traveling cold front swept across the continent, and moved eastward. Figs. 4d and 5d clearly show strong continental outflow from eastern and northeastern China and Korea associated with the front. We find a belt of elevated SO$_4^{2-}$/C$_0$ concentrations in the fore part of the front in Fig. 5d and this belt vertically can extend to 2 km high (Fig. 5f), where high water contents and cloud processes associated with frontal uplifting lead to increase in SO$_4^{2-}$ production, and low SO$_4^{2-}$/C$_0$ concentrations in the back part the front due to the subsidence of cool, dry and SO$_4^{2-}$/C$_0$ poor air, even SO$_2$ mixing ratios are high (>2 ppbv) there (Figs. 4d and f). High SO$_2$ values were recorded at Hedo in the next several days (Fig. 2a).

In this section we find that the model reproduces the observed variations of SO$_2$ and SO$_4^{2-}$/C$_0$ concentrations well, and in most cases simulated and observed values are in good agreement. Analysis of model results shows that the Miyakejima volcano emissions have strong influence upon SO$_2$ and SO$_4^{2-}$/C$_0$ levels around Japan, and the SO$_2$ and SO$_4^{2-}$/C$_0$ concentrations exhibit pronounced variations in time and space, with SO$_2$ and SO$_4^{2-}$/C$_0$ behaving differently.

### 3.2. Vertical concentration distributions of SO$_2$ and SO$_4^{2-}$/C$_0$ along the flight tracks

During the ACE-Asia missions, instrumented NCAR aircraft C-130 conducted extensive flights over the Yellow Sea, the Sea of Japan and south of Japan, and here we present three typical flights to show vertical distributions of SO$_2$ and SO$_4^{2-}$/C$_0$ concentrations over these areas. Figs. 7–9 show C130 flight tracks conducted in the period of 11–13 April and time series of observed and simulated SO$_2$ and SO$_4^{2-}$/C$_0$ concentrations along the flight tracks. SO$_2$ measurements were made by an atmospheric pressure ionization mass spectrometer (APIMS) (Mitchell, 2001) and airborne measurements of SO$_4^{2-}$ were analyzed by using a particles-into-liquid-sampler (PILS) (Weber et al., 2001). In these figures the observed SO$_2$ and SO$_4^{2-}$ concentrations were 5 min averaged, while the model results were sampled along the flight tracks with a 1 h temporal resolution.

On 11 April (RF06) and 12 (RF07), C-130 made extensive observations over the Yellow Sea. It took off at about 0900 JST from the Marine Corps Air Station Iwakuni, located on the west side of main island of Honshu, Japan, and firstly headed westward and then northward (Figs. 7A and 8A). The measured SO$_2$ and SO$_4^{2-}$/C$_0$ concentrations (Figs. 7B, C, 8B and C) exhibit large variations in time and space and show high values and good correlation between them in the lower troposphere (below 2 km), as SO$_2$ is mostly emitted in the continental boundary layer and SO$_2$ and SO$_4^{2-}$/C$_0$ levels over the Yellow Sea depend primarily on transport processes of SO$_2$ and SO$_4^{2-}$/C$_0$ and chemical conversion of SO$_2$ to SO$_4^{2-}$. At an altitude above 2 km, SO$_2$ mixing ratios were quite low, and SO$_2$ and SO$_4^{2-}$/C$_0$ do not show any correlation, which may be due to the depletion of SO$_2$. 

![Flight track (A) and time series of observed (solid dots) and modeled (open triangles) SO$_2$ (B) and SO$_4^{2-}$/C$_0$ (C) mixing ratios of C130 flight RF 06 conducted on 11 April. The numbers in plot A are JST, and the flight altitude is shown by a dashed line in plots B and C.](image-url)
On 13 April (RF08), C-130 started observations at about 0900 JST, and firstly flew northeastward and then southwestward (Fig. 9A). SO$_2$ levels measured during the flight were lower over the Yellow Sea than that obtained in previous flights, while SO$_4^{2-}$ levels were higher, as part of SO$_2$ was converted to SO$_4^{2-}$ during transport processes (see Figs. 4 and 5). It is important to point out that the modeled SO$_4^{2-}$ is underestimated (about 2-3 $\mu$g/m$^3$) during the time between 1230 and 1530 JST when C-130 flew over the east edge of East China sea (Fig. 9A). However, we can see the high SO$_4^{2-}$ region is just west of the flight area (Fig. 9e), so the reason of this underestimation can be understood as model horizontal resolution.

From Figs. 7-9 we find that the modeled and observed SO$_2$ to SO$_4^{2-}$ concentrations are generally in good agreement, and the model reproduces time and space variations in SO$_2$–SO$_4^{2-}$ reasonably well.

3.3. Process analysis for sulfur compounds

SO$_4^{2-}$ is primarily produced from the oxidation of SO$_2$, and the conversion of SO$_2$–SO$_4^{2-}$ occurs via multiple pathways, including gas-phase oxidation to H$_2$SO$_4$ followed by condensation into the particulate phase, aqueous phase oxidation in cloud or fog droplets, and various reactions on the surfaces or inside aerosol particles. For illustrating the impacts of the emissions, as well as various transport and chemical processes, upon SO$_2$ and SO$_4^{2-}$ concentrations, a processes analysis was performed. In Table 1 the sources and sinks of SO$_2$, H$_2$SO$_4$ and SO$_4^{2-}$ in the whole model domain below 16 km in the period from 1 March to 30 April of 2001 are summarized. In the Table TRT includes the contributions from transport and diffusion processes, CHEM stands for the gas-phase chemical production, AQUE accounts for the impacts of aqueous chemistry and cloud processes, G2P represent SO$_4^{2-}$ production via
Table 1
Sources and sinks of SO₂, H₂SO₄, and SO₄²⁻ in the whole model domain below 16 km (6240 × 5440 × 16 km³) in the period 1 March–30 April of 2001 (Unit: 10¹⁰ gS)

In the Table TRT includes the contributions from transport and diffusion processes, CHEM stands for the gas-phase chemical production, AQUE accounts for the impacts of aqueous chemistry and cloud processes, G₂P represent SO₄²⁻ production via the gas to particle processes, EMIS stands for emissions, and DRY and WET are for dry and wet deposition. Negative values indicate the mass of the species decreased by this processes.

The SO₂ and SO₄²⁻ emissions from the Miyakejima volcano played a very important role in forming high levels of SO₂ and SO₄²⁻ around Japan as recorded at the four remote sites of Oki, Hoppo, Sado, and Hedo and on board Ship RonBrown in the period 9–13 April.

Analysis of sulfur budgets in the period 1 March–30 April indicates that the gas phase and the aqueous phase have the same importance in oxidizing SO₂ (~68% via the aqueous phase) in the model domain, and about 42% of sulfur compounds (~25% in SO₂) emitted in the domain is transported out of the model domain, while about 57% (~35% by wet removal processes) is deposited in the domain.

4. Conclusions

The Models-3 CMAQ modeling system with meteorological fields calculated by the Regional Atmospheric Modeling System (RAMS) was applied to East Asia to investigate the transport and chemical transformation processes of SO₂ in the springtime of 2001. Comparison of simulated concentrations of SO₂ and SO₄²⁻ with surface observations at four remote sites in Japan and airborne and ship measurements during TRACE-P and ACE-Asia indicates that CMAQ reproduces many of the important features in the observations, including horizontal and vertical gradients. The SO₂ and SO₄²⁻ concentrations show pronounced variations in time and space, with SO₂ and SO₄²⁻ behaving differently due to the interplay of chemical conversion, removal and transport processes.
